(Received 4 June 2018; accepted 8 October 2018; published online 2 November 2018)

We show that a rigid scissors-like GW self-consistency approach, labeled here $\Delta GW_0$, can be trivially implemented at zero additional cost for large scale one-shot $G_0W_0$ calculations. The method significantly improves one-shot $G_0W_0$ and for large systems is very accurate. $\Delta GW_0$ is similar in spirit to evGW0 where the self-consistency is only applied on the eigenvalues entering Green’s function, while both W and the eigenvectors of Green’s function are held fixed. $\Delta GW_0$ further assumes that the shift of the eigenvalues is rigid scissors-like so that all occupied states are shifted by the same amount and analogously for all the unoccupied states. We show that this results in a trivial modification of the time-dependent $G_0W_0$ self-energy, enabling an a posteriori self-consistency cycle. The method is applicable for our recent stochastic-GW approach, thereby enabling self-consistent calculations for giant systems with thousands of electrons. The accuracy of $\Delta GW_0$ increases with the system size. For molecules, it is up to 0.4-0.5 eV away from coupled-cluster single double triple (CCSD(T)), but for tetracene and hexacene, it matches the ionization energies from both CCSD(T) and evGW0 to better than 0.05 eV. For solids, as exemplified here by periodic supercells of semiconductors and insulators with 6192 valence electrons, the method matches evGW0 quite well and both methods are in good agreement with the experiment. I. INTRODUCTION

The $GW$ approximation1 to many-body perturbation theory is often used to calculate electron removal or addition energies and the related (inverse) photoemission spectra of molecules, nanostructures, and bulk materials.2–15 $GW$ is part of a family of methods that describe the probability amplitude of a quasiparticle (QP) to propagate between two space-time points $(\mathbf{r},t)$ and $(\mathbf{r}',t')$ with Green’s function $G(\mathbf{r},\mathbf{r}',t,t')$, the poles of which are the QP energies. Green’s function is obtained perturbatively from reference (non-interacting) Green’s function, $G_0(\mathbf{r},\mathbf{r}',t,t')$, via a Dyson equation (all equations use atomic units),

$$G(\mathbf{r},\mathbf{r}',t,t') = G_0(\mathbf{r},\mathbf{r}',t,t') + \int \int G_0(\mathbf{r},\mathbf{r}_1,t,t_1) \times \Sigma(\mathbf{r}_1,\mathbf{r}_2,t_1-t_2)G(\mathbf{r}_2,\mathbf{r}',t_2,t')d\mathbf{r}_1dt_1d\mathbf{r}_2dt_2,$$

where $\Sigma(\mathbf{r}_1,\mathbf{r}_2,t)$ is the time-dependent self-energy. Reference Green’s function is typically3,16,17 given by the Kohn-Sham18 (KS) density function theory (DFT).19 In $GW$, the self-energy $\Sigma$ is approximated as

$$\Sigma(\mathbf{r},\mathbf{r}',t) = iG(\mathbf{r},\mathbf{r}',t)W(\mathbf{r},\mathbf{r}',t'),$$

where $W(\mathbf{r},\mathbf{r}',t)$ is the screened Coulomb interaction, usually evaluated within the random phase approximation (RPA).

A solution of the equations above requires in principle a self-consistent procedure since both $\Sigma(\mathbf{r},\mathbf{r}',t)$ and $W(\mathbf{r},\mathbf{r}',t')$ depend on $G(\mathbf{r},\mathbf{r}',t)$. In practice, the self-consistency is often abandoned and the most common $GW$ treatment is based on “one-shot” scheme,16,17 $G_0W_0$, where the right hand side of Eq. (2) becomes $G_0(\mathbf{r},\mathbf{r}',t)W_0(\mathbf{r},\mathbf{r}',t)$ and $W_0$ is obtained from a random phase approximation that uses the KS eigenstates. The one-shot approach improves significantly the KS-DFT results, yet it depends on the choice of the reference system and often underestimates the QP gaps ($E_g$) and the ionization potentials ($I$).8,20–25 A fully self-consistent solution is computationally extremely demanding,10,21,26–33 and in many situations, it yields results that are worse than $G_0W_0$.8,34,35

Heuristically, since $GW$ is an approximation, an iteration of that approximation may enhance the deviation from the exact result.

To simplify the problem, a static and Hermitian approximation to the self-energy20,36 is sometimes used in the so-called QP self-consistent $GW$ (qpGW), which iteratively updates the $\Sigma$ and QP wave-functions (i.e., the Dyson orbitals). The qpGW approach is still computationally expensive and cannot be applied for large systems; furthermore, it tends to
overestimate $E_g$ and the ionization potential,\textsuperscript{35–37} due to an overly strong screened Coulomb interaction.\textsuperscript{15,35,36} Alternatively, the $W$ term is kept “frozen” and self-consistency is sought only in Green’s function.\textsuperscript{6,27,28,35,38} This method is termed eigenvalue self-consistent GW ($\text{evGW}_0$), and it was applied successfully to bulk systems\textsuperscript{35,40} and to organic molecules.\textsuperscript{25,27,28} Despite the lack of self-consistency in $W$, which leads to overscreening (since it is based on an underestimated KS DFT gap)\textsuperscript{35} and non-negligible starting point dependence,\textsuperscript{41,42} $\text{evGW}_0$ provides a reasonable route for improving the “one-shot” predictions or gaps in extended systems, notwithstanding the fact that for fairly small molecular systems the starting-point dependence is very large.

While overall self-consistency methods provide an improvement over one-shot $G_0W_0$, there is an issue of scaling and overall cost. Even one-shot $G_0W_0$ has usually been quite expensive, scaling as $O(N^3_e) - O(N^4_e)$ with the number of electrons $N_e$ and self-consistency methods at least multiply the cost by the number of iterations. Thus, in spite of their potential, $G_0W_0$ and its self-consistent improvements were only applicable to fairly small systems unless drastically loose computational efforts are used, and even then large systems with many thousands of electrons were not feasible.

Recently, however, we developed an effectively linear-scaling stochastic approach to $G_0W_0$ with moderate computational cost.\textsuperscript{43–45} The approach has been verified to give the same results as deterministic converged-basis (or converged plane-wave) $G_0W_0$ simulations and can handle systems with more than 10 000 electrons.\textsuperscript{45} But as stochastic $G_0W_0$ obtains directly only a column of the self-energy matrix rather than the full-matrix, most self-consistent improvements cannot be applied to it.

Here, we enhance the power of the stochastic approach, by showing that a variant of $\text{evGW}_0$ whereby the energies of the HOMO and LUMO are shifted rigidly (a scissors operator for Green’s function) is labeled $\text{GW}_0$ and its self-consistent improvements were only consistently obtained in Green’s function.\textsuperscript{8,27,28,35,38} We now show that stochastic $\text{evGW}_0$ provides a reasonable route for improving the “one-shot” predictions or gaps in extended systems, where the energies of the HOMO and LUMO are shifted rigidly (a scissors operator for Green’s function).

The paper is organized as follows: Sec. II presents the theory. Sec. III presents the results for molecules and solids, and conclusions follow in Sec. IV.

II. THEORY

A. Green’s function self-consistency in the time domain

The QP energy of the $i$th state $E^{QP}(i)$ is calculated using the usual form of the perturbative GW approximation in which the Kohn-Sham eigenvalues ($\epsilon^0(i)$) are corrected by the QP shift ($\Delta(i)$) using a fixed point equation,

$$E^{QP}(i) = \epsilon^0(i) + \Delta(i),$$

where

$$\Delta(i) = \Sigma(i) = \int \langle \phi_i | \Sigma (\omega) | \phi_i \rangle e^{-i\omega t} dt,$$

and $\Sigma(i)$ is given by Eq. (2).

Starting from a KS DFT reference point, the initial self-energy is constructed from the KS propagator

$$iG_0(r, r', t) = \text{Tr}\left\{ \langle r' \rangle \langle r | e^{-i\hat{H}t} \left[ \theta(t) \theta(\mu - \hat{H}^0) \right] \right\},$$

where $\text{Tr}$ denotes a trace over all KS states, $\mu$ is the chemical potential, $\theta$ is the Heaviside step function that guarantees forward and backward time propagation for particles and holes, respectively, and $\hat{H}^0$ is the KS Hamiltonian,

$$\hat{H}^0 = -\frac{1}{2} \nabla^2 + v_{\text{ext}} + v_{\text{H}} + v_{\text{xc}},$$

where we introduced the kinetic energy and the external and Hartree potentials. In the rest of the paper, we employ real time-dependent Hartree propagation to calculate the screened Coulomb interaction;\textsuperscript{43,44} this is equivalent to using the RPA approximation for $\hat{G}_0$.

In the time-domain, the self-energy matrix element for the $i$th state is

$$\langle \phi_i | \Sigma(t) | \phi_i \rangle$$

$$= i \int \phi_i(r) G_0(r, r', t) W_0(r, r', r') \phi_i(r') d^3r,$$

where $W_0$ is the Wannier matrix.

In the $\text{evGW}_0$ procedure, Green’s function is reconstructed in each iteration, employing the QP energies from
the previous iteration. In the time domain, this corresponds to writing the propagator as
\[
iG(r, r', t) = \text{Tr} \left[ |r\rangle \langle r'| e^{-i[H_0 + \hat{\Lambda}^t]} \right] \\
\times \left\{ \theta(t) \theta_H (\tilde{h}^0 - \mu) - \theta(-t) \theta_H (\mu - \tilde{h}^0) \right\}, \tag{9}
\]
where \( \hat{\Lambda} \) contains all the many-body contributions to the spectrum.

As common in evGW\(_0\) self-consistency,\(^{8,35,38}\) for the purpose of Eq. (9), one ignores the non-Hermiticity of the self-energy and treats it as diagonal so that in the KS basis the correction operator is approximated as
\[
\hat{\Lambda} \approx \sum_i |\phi_i\rangle \text{Re} \Delta(i) \langle \phi_i|.
\tag{10}
\]
Hence, all the KS energies in the exponent in Eq. (9) are shifted to the QP energies obtained from Eq. (3). Equation (10) is the fundamental equation of evGW\(_0\).

Since \( \hat{\Lambda} \) in Eq. (9) is by construction diagonal in the KS basis set, we view it as a function of the KS Hamiltonian \( \hat{\Lambda}(\tilde{h}^0) \) that interpolates all QP shifts. Green’s function is therefore
\[
iG(r, r', t) = \text{Tr} \left[ |r\rangle \langle r'| e^{-i[H_0 + \hat{\Lambda}(\tilde{h}^0)]} \right] \\
\times \left\{ \theta(t) \theta_H (\tilde{h}^0 - \mu) - \theta(-t) \theta_H (\mu - \tilde{h}^0) \right\}.
\tag{11}
\]
This simple expression allows for a further approximation described below that significantly reduces the computational cost associated with self-consistent treatment.

**B. Efficient implementation**

In many cases, \( \hat{\Lambda} \) is well described by a low degree polynomial with discontinuity only at the bandgap energies, \( \varepsilon(H) \) and \( \varepsilon(L) \), corresponding to the highest occupied (H) and lowest unoccupied (L) states, respectively. The zeroth order term in this polynomial is a scissors operator\(^{46,47}\) which shifts the occupied and unoccupied states down and up in energy, respectively,
\[
\text{Re} \Delta \left[ \varepsilon^0(i) \right] \approx \begin{cases} 
\Delta(H) & \varepsilon^0(i) \leq \varepsilon^0(H) \\
\Delta(L) & \varepsilon^0(i) \geq \varepsilon^0(L).
\end{cases}
\tag{12}
\]
We call this approximation \( \DeltaGW_0 \) and use it in Sec. III for molecules and periodic systems. Furthermore, rather than choosing highest occupied and lowest unoccupied states, \( \text{Re} \Delta \) may be taken based on an average shift of all occupied and unoccupied states, respectively.

Combining Eqs. (12) and (11) leads to modified Green’s function which acquires an additional phase shift that is different for positive and negative times. Therefore, in the time domain, we define
\[
\hat{\Delta}(t) \equiv \begin{cases} 
\Delta(H) & t < 0 \\
\Delta(L) & t > 0.
\end{cases}
\tag{13}
\]
In each iteration, the updated self-energy matrix element is then calculated as
\[
\langle \phi_i | \hat{\Sigma}(t) | \phi_j \rangle = e^{-i\hat{\Delta}(t)} \langle \phi_i | \hat{\Sigma}_0(t) | \phi_j \rangle.
\tag{14}
\]
Next, the self-energy matrix element is transformed to the frequency domain and used in Eq. (3) to calculate a new estimate of the QP energy. The new QP energy is used iteratively to update Eqs. (12) and (13). The full cycle is illustrated in Fig. 1.

Note that this form of self-consistency is trivial and is a postprocessing step with no additional cost, unlike previous uses\(^{46,47}\) of the scissors-operator in GW which require repeated evaluations of the self-energy. Furthermore, the \( \DeltaGW_0 \) approach is applicable to any implementation which yields \( \hat{\Sigma}[\omega] \) for the HOMO and LUMO states. Thus, this method is naturally suited for the stochastic \( G_0W_0 \) method\(^{43-45}\) which provides the self-energy over the full-time domain and therefore over a wide range of frequencies (spanning several hundred eV). Note that while in principle one could use higher order polynomials of \( \Delta \), and such polynomials would generally require going beyond a post-processing method, i.e., would require additional GW calculations.\(^{48}\) Therefore, the simple equation (14), for a scissors-type expression, is our main result.

**III. RESULTS AND DISCUSSION**

**A. Molecules**

We first test our approach on ionization potentials \( I \) [taken as the negative of the HOMO energy, \( -\varepsilon(H) \)] for a set of small molecules listed in Table I. A ground state DFT calculation is performed using a Fourier real-space grid, ensuring (through the Martyna-Tuckerman approach)\(^{39}\) that the potentials are not periodic. The exchange-correlation interaction is described by the local density approximation (LDA)\(^{50}\) with Troullier-Martins pseudopotentials;\(^{51}\) the DFT eigenvalues are converged up to \( <10 \) meV with respect to the spacings of the real space grids (given in Table I).

Six molecules were tested, ranging in size from \( N_2 \) to hexacene. In all cases, stochastic \( G_0W_0 \)\(^{43-45}\) was used to calculate the self-energy; \( \DeltaGW_0 \) converges in 3-4 iterations after the initial \( G_0W_0 \) calculation; the self-energy curves are illustrated for hexacene in Fig. 2. Since our self-consistency procedure is performed \textit{a posteriori}, its computational cost is negligible (less than a second on a single core machine).

In all cases, \( \DeltaGW_0 \) increases the ionization potentials above the one-shot values. This is a desired outcome since \( G_0W_0 \) underestimates \( I \).\(^{24,42,44}\)
TABLE I. Ionization potentials $I$ for small molecules by different methods. The $G_0W_0$ and $\Delta GW_0$ estimates were obtained using an LDA starting point and calculated through a stochastic implementation, and the statistical errors are reported in parentheses; evGW and qpGW refer to eigenvalue self-consistency and full self-consistency, respectively, based on a PBE starting point and for the first three molecules (the non-acenes) are not extrapolated to the infinite basis-set limit. Experimental values are from Ref. 56. For the acenes, the CCSD(T) results are estimates extrapolated to the infinite basis-set limit. The last two columns show the difference between the partially self consistent values (for the present $\Delta GW_0$ and for evGW) and the starting $G_0W_0$ energies. Molecular geometries were taken from Refs. 56 and 42.

Table I shows the ionization energies at several levels, including $G_0W_0$, $\Delta GW_0$, deterministic self-consistent GW on two levels, CCSD(T), and also the experiment.

The $G_0W_0$ column shows our stochastic $G_0W_0$ values that are fully converged with grid size (i.e., in a plane-wave language, corresponding to a fully converged plane-wave cutoff) and are therefore close to the converged deterministic plane-wave basis results benchmarked in Ref. 52 as well as basis set extrapolated values obtained with deterministic codes, with differences of typically less than 0.1 eV, which are mostly due to the use of an LDA functional rather than PBE exchange-correlation functional.

Our partially self-consistent $\Delta GW_0$ is then compared in the table to other partially self-consistent techniques in the literature, suitable for small molecules. The most direct comparison should be to evGW, where, as mentioned, Green’s function is also converged (leaving $W_0$ frozen at its initial value), for an initial Hamiltonian with a local potential. There are large deviations for the small molecules (0.6–0.7 eV), and there are several contributing factors to these differences. First, for the three small molecules about 0.1-0.2 eV difference is due to the non-completeness of the basis set (see Ref. 24 for the effect of basis-set extrapolation). For nitrogen and urea, another factor of ≈0.1 eV is due to our use of LDA rather than PBE in the quoted evGW results. Taken together, this still leaves about an error of ≈0.4 eV between our results and evGW for the small molecules.

The difference between the present $\Delta GW_0$ and evGW is made more explicit by the last two columns in Table I, which shows the degree of correction due to self-consistency (i.e., the difference between the final result and the one-shot $G_0W_0$) for our calculation and evGW. For the small molecules, $\Delta GW_0$ gives a correction which is higher than evGW by more than 0.4 eV. But for larger systems, the deviation is getting much smaller. Specifically, the deviation from $\Delta GW_0$ decreases to 0.1–0.25 eV for the three larger molecules (three acenes) where the deterministic basis-set results for the acenes were already extrapolated to the infinite basis-set limit. A small portion of the difference is due to our use of LDA rather than PBE. Overall the much better agreement of the rigid-shift approach with evGW for large systems is due to the improved assumption of a rigid shift.

A separate question from the agreement of the rigid-shift approximation with evGW is how accurate the overall method is, i.e., does the method agree with more exact non-GW approaches. Here, the comparison with the CCSD(T) ionization energy (extrapolated to the limit of infinite basis-set) is quite encouraging. For the small molecules, there is a large deviation from CCSD(T), but it decreases dramatically to 0.15 eV and below once we go to the larger acenes.

Interestingly, $\Delta GW_0$ is generally closer to the CCSD(T) results than evGW. This is probably due to error cancellation; i.e., evGW based on a local potential somewhat underestimates the CCSD(T) results, and $\Delta GW_0$ generally somewhat overestimates evGW due to the rigid shift assumption. Nevertheless, Table I does show that for the ionization energy, as the system size grows the essentially exact CCSD(T) is better and better predicted by both the evGW approximation and our $\Delta GW_0$ further approximation to evGW. Likewise, $\Delta GW_0$ agrees well with the experiment for the larger molecules.

TABLE II. Fundamental bandgaps (Eg) for a sample of solids. For each system, a 6 × 6 × 6 conventional super-cell (with 6192 valence electrons) was used.

We conclude this section by a cautionary note. The success of both evGW0 based on a local potential and ∆GW0 is for the ionization potential. For the LUMO, i.e., for the electron affinity, the results of both evGW0 and ∆GW0 are not as good (deviations of more than 0.5 eV from the exact results even for the larger systems). For the LUMO, a time dependent DFT (TDDFT)-based kernel may give better one-shot results, and the application of rigid-shift self-consistency for the LUMO would be described in a future publication.

B. Periodic systems

Next we study self-consistency for periodic solids, using an extension of the stochastic GW approach to treat periodic boundary conditions. The self-consistent ∆GW0 method is demonstrated on large supercells with 1712 atoms (corresponding, for the system we study below, to 6 × 6 × 6 conventional cells with 6912 valence electrons). The stochastic approach handles well such large system sizes, yielding again self-energies for selected electronic states. Here we are interested in the fundamental bandgap, Eg = ε(L) − ε(H), so we need both the highest occupied and lowest unoccupied states. For large extended systems, the complications associated with a TDDFT vs. RPA based kernel are tamed in comparison with molecules, so it makes sense to study the gap, based solely on RPA.

Table II shows for several solids the one-shot and ∆GW0 and compares them again to previous self-consistent GW calculations and to experiment. The results demonstrate first that the one-shot correction yields bandgaps that are mostly (though not always) lower than experimental values, in agreement with previous calculations.

Moving to ∆GW0, in all cases studied, self-consistency is quickly achieved within 2 or 3 iterations and the self-energy curves are illustrated in Fig. 3. The fundamental bandgaps are enlarged by as much as 0.17 eV compared to GoW0. For all the solids in Table II, the difference between the QP shifts for the bottom and top valence states is small (correlating slightly with Eg) and similar in magnitude for all states. The underlying assumption that all states in either the occupied or unoccupied subspace are shifted (approximately) by a constant is fulfilled well.

![Graphical solution to the EQ equation for the GoW0 and ∆GW0 self-energies, for a diamond solid simulated by a 6 × 6 × 6 supercell. The gray line denotes the frequency, and the intersections with the black and red lines are the solution to the fixed point equation [Eq. (3)]. The full and dashed lines are for the top valence and bottom conduction states, respectively. Both axes are shifted so that zero is associated with the original LDA top of the valence band.](image-url)
Gaps predicted by $\Delta GW_0$ are similar to previously published evGW results.\textsuperscript{59} Much of the difference is due to the use of distinct atomic potentials in previous calculations, which are known to cause energy differences up to $\sim 0.2$ eV.\textsuperscript{60} More importantly for our purpose, here are the energy differences due to the self-consistency (i.e., the differences of either evGW\textsubscript{0} or $\Delta GW_0$ energies from $G_0W_0$). These differences (which are less sensitive to the particular type of potentials used) are very close, to within about 0.04 eV in average.

In Table II, we also list experimental bandgaps. Such comparison has to be performed with caution since our calculations do not account for renormalization of $E_g$ due to zero-point motion,\textsuperscript{61} which decreases the gap by as anywhere from 0.05 eV (silicon) to 0.37 eV (diamond).\textsuperscript{62} Yet it is encouraging to see that $\Delta GW_0$ enlarges $E_g$ and that our predictions are quite close to experimental values.

IV. SUMMARY AND CONCLUSIONS

We derived here a general form of Green’s function self-consistency in the time domain and introduced its simplified form, which we label $\Delta GW_0$. The starting point is the scissors correction, where the differences between Kohn-Sham eigenvalues and quasiparticle energies are approximately just two constants, one for occupied and the other for unoccupied states. We approximate this scissors-like correction by the corrections to the HOMO and LUMO energies. But unlike previous self-consistency schemes (even those relying on scissors-like operators), our approach does not require repeated many-body calculation and uses only two self-energy matrix elements. Practically, it is merely an a posteriori treatment of the time-dependent self-energy matrix. Yet, it captures the major changes in the structure of Green’s function and hence of the self energy for large systems.

$\Delta GW_0$ has essentially no additional computational cost beyond that of a one-shot $G_0W_0$ calculation. In conjunction with the nearly linear scaling stochastic $G_0W_0$, it can treat extremely large systems with thousands of electrons. The combined method is best labeled as stochastic $\Delta GW_0$.

We tested stochastic $\Delta GW_0$ on molecules and on periodic semiconductors and insulators with large periodic supercells with 6192 electrons. The predicted ionization potentials and fundamental bandgaps are overall better than one-shot $G_0W_0$ values when compared to high-level methods and/or experiments. Our simplified self-consistency treatment is especially appropriate for large molecules and periodic systems, for which no other computationally affordable approach existed up to now.

$\Delta GW_0$ is an approximation on top of another, successful approximation, evGW\textsubscript{0}. For small systems, both approximations have faults (dependence on initial DFT Hamiltonian in the final results of evGW\textsubscript{0}, compounded by strong state dependence of the self-energy diagonal elements violating the underlying assumption on $\Delta GW_0$). But the purpose of the new approach is to address very large systems, for which these two issues are much less severe, and for which $\Delta GW_0$ is automatically suited, since, unlike even evGW\textsubscript{0}, it does not require the computation of new operators when the quasi-particle energies are updated.

The stochastic partially self-consistent $\Delta GW_0$ approach presented here is both accurate for large systems and efficient, opening the door to many future applications in chemistry, physics, and nano- and material sciences.
