Calculation of the cumulative reaction probability via a discrete variable representation with absorbing boundary conditions

Tamar Seideman and William H. Miller
Department of Chemistry, University of California, Berkeley, California 94720
(Received 13 November 1991; accepted 9 December 1991)

A new method is suggested for the calculation of the microcanonical cumulative reaction probability via flux autocorrelation relations. The Hamiltonian and the flux operators are computed in a discrete variable representation (DVR) and a well-behaved representation for the Green’s operator, \( G(E^+) \), is obtained by imposing absorbing boundary conditions (ABC). Applications to a one-dimensional-model problem and to the collinear \( \text{H} + \text{H}_2 \) reaction show that the DVR-ABC scheme provides a very efficient method for the direct calculation of the microcanonical probability, circumventing the need to compute the state-to-state dynamics. Our results indicate that the cumulative reaction probability can be calculated to a high accuracy using a rather small number of DVR points, confined to the vicinity of the transition state. Only limited information regarding the potential-energy surface is therefore required, suggesting that this method would be applicable also to higher dimensionality problems, for which the complete potential surface is often unknown.

1. INTRODUCTION

It is well recognized that only a quantum-mechanical scattering calculation provides all the attributes of a bimolecular chemical reaction, i.e., state-to-state differential and integral cross sections. However, one is often interested in much less detailed quantities, e.g., the thermally averaged rate constant for the reaction. There is thus considerable interest in theoretical approaches that allow one to calculate the rate constant directly, i.e., without having to first solve the complete state-to-state reactive scattering problem, but nevertheless rigorously.

Reactive flux correlation functions do, in fact, provide a means for such a direct calculation.\(^1\) Most of the recent effort along these lines has focused on the flux-flux autocorrelation function \(^2\)

\[
C_f(t) = \text{tr} \left[ F e^{i H t / \hbar} F e^{-i H t / \hbar} \right],
\]

(1.1a)

the time integral of which gives the rate constant

\[
k(T) = Q(T)^{-1} \int_0^\infty dt C_f(t).
\]

(1.1b)

[\( H \) in Eq. (1.1a) is the total Hamiltonian of the molecular system, \( F \) a flux operator (see Sec. II), \( t_c = t - i \hbar / 2 \kappa T \), \( T \) the temperature, \( Q \), the reactant partition function per unit volume, and \( \text{tr} \) denotes a quantum mechanical trace.] This paper, however, deals with a direct calculation of the cumulative reaction probability, \( N(E) \), the Boltzmann average of which gives the thermal rate constant,

\[
k(E) = \left[ 2 \pi \rho_0(E) \right]^{-1} N(E),
\]

(1.3)

where \( \rho_0 \) is the density of reactant states per unit energy.

The primary definition of the cumulative reaction probability is as the sum of reaction probabilities (squares of \( S \)-matrix elements) over all internal (rotational and vibrational) states of reactants and products\(^2\)

\[
N(E) = \sum_{n\alpha} |S_{n\alpha}|^2,
\]

(1.4)

where \( n \) and \( \alpha \) denote the collection of asymptotic quantum numbers of the reactants and products, respectively. Although one can calculate \( N(E) \) via Eq. (1.4) once a reactive scattering calculation has been carried out to obtain the \( S \) matrix, it obviously does not provide a direct approach to \( N(E) \) because one must first obtain all the state-to-state information (i.e., the \( S \) matrix) which is then averaged to obtain \( N(E) \). There does, however, exist a “direct” expression for \( N(E) \), derived from the flux correlation function analysis\(^2\)

\[
N(E) = \frac{1}{4 \pi} \text{Im} \text{tr} \left[ F \delta(E - H) F \delta(E - H) \right],
\]

(1.5a)

the evaluation of which is the subject of this paper. \( F \) in Eq. (1.5a) is the same flux operator as in Eq. (1.1a), and the microcanonical density operator is usually obtained from the outgoing wave Green’s function

\[
\delta(E - H) = -\frac{1}{\pi} \text{Im} G(E^+)
\]

(1.5b)

Equation (1.5) is equivalent to Eq. (1.4), but it has the advantage of no reference to asymptotic quantum states.

Thirumalai, Garrett, and Berne\(^{10(a)}\) have previously attacked the evaluation of Eq. (1.5a) using a finite Gaussian approximation for the \( \delta \)-function operator [i.e., \( \delta(z) \)]
formal convergence factor used in defining the Green's function in Eq. (1.5b)) which can also be represented in terms of the time evolution operator,
4414 T. Seideman and W. H. Miller: Calculation of cumulative reaction probability

\[ T_{\beta \alpha}^{a} = \sum_{a=1}^{g} T_{\beta \alpha}^{a} \prod_{\beta=1}^{g} \delta_{\alpha \beta} \]  (2.3b)

each of which is given by

\[ T_{\beta \alpha}^{a} = \frac{\hbar^2}{2m_{a} \Delta q_{a}^2} (-1)^{j_{j}} \left[ \frac{\pi^2 / 3}{(j - j')^2} \right] \]  (2.3c)

The Hamiltonian matrix \( H_{\beta \alpha}^{a} \) is thus very easy to construct and is extremely sparse.

The infinite grid defined by Eq. (2.2) is next adapted to the shape of the potential surface by using an energy cutoff criterion, \[ V(q) \leq K \] (2.4), i.e., only grid points for which \( V(q) \leq K \) are retained, where \( V_{c} \) is the cutoff value of the potential energy. Since the points that are discarded are in a classically forbidden regime for states with energies lower than \( V_{c} \), the grid generated by Eq. (2.4) will provide an accurate description of all states with energies sufficiently below \( V_{c} \). The energy cutoff provides a very simple way of generating points that follow the shape of a given potential-energy surface, and convergence is easily checked by increasing the value of \( V_{c} \).

The flux operator \( F \) is defined in terms of a surface in coordinate space that separates reactants from products. It is specified most generally by equating some function of coordinates to zero,

\[ f(q) = 0. \] (2.5a)

A simple example of this is

\[ f(q) = q_{F}, \] (2.5b)

i.e., the \( F \) - 1 dimensional surface on which the reaction coordinate \( q_{F} \) is constant (here zero). The flux operator is then given by

\[ F = \frac{1}{\hbar} \{ H, h[f(q)] \}, \] (2.6a)

where \( H \) is the total Hamiltonian and \( h \) is the Heaviside function

\[ h(\xi) = \begin{cases} 1, & \xi > 0 \\ 0, & \xi < 0 \end{cases} \] (2.6b)

[One recognizes Eq. (2.5a) as the Heisenberg time derivative, \( F = (d/dt) h(f(q)) \).] Since \( h[f(q)] \) is a function of coordinates, the potential-energy part of \( H \) commutes with it, so that Eq. (2.6a) becomes

\[ F = \frac{1}{\hbar} \{ T, h(f(q)) \}. \] (2.6c)

For the simple choice of \( f(q) \) in Eq. (2.5b), Eq. (2.6c) reduces to

\[ F = \frac{1}{2} \left[ \frac{p_{F}}{m} \delta(q_{F}) + \delta(q_{F}) \frac{p_{F}}{m} \right], \] (2.6d)

a form that has been used in most calculations to date for the reactive flux.\(^{2(1), 11}\)

However, rather than using Eq. (2.6d) for the flux operator, in this paper we utilize Eq. (2.6c). Not only is it more general, but we have also found it to give much more rapid convergence in terms of grid size. The DVR for the flux operator, Eq. (2.6c) is thus

\[ F_{ij} = \frac{i}{\hbar} T_{ij}^{a} \{ h[f(q_{j})] - h[f(q_{j})] \}, \] (2.7)

showing explicitly that in addition to the grid point representation of the kinetic energy—which is already at hand from construction of the Hamiltonian—one only needs to evaluate the function \( f(q) \) at the various grid points to see if \( f > 0 \) or \( f < 0 \). Equation (2.7) shows that the flux matrix element is nonzero only if the grid points \( q_{j} \) and \( q_{j'} \) are on opposite sides of the dividing surface.

The version of the DVR for the flux operator based on Eq. (2.6d) is given in Appendix A.

B. Absorbing boundary conditions

As discussed in Sec. I regarding Eqs. (1.6)-(1.9), a function \( \epsilon(q) = \Gamma(q) / 2 \) is introduced which is essentially zero in the physically relevant interaction region and turns on at the edge of the DVR grid. Since \( -i \epsilon(q) \) is a potential-energy-like term, its DVR is diagonal and simply added to the potential matrix of Eq. (2.3a).

We first consider the form of the absorbing potential in the one-dimensional case

\[ \epsilon(q) = \epsilon(q), \] (2.8)

where \( q = 0 \) is the transition state (and location of the dividing "surface"). Denoting by \( q_{\text{max}} \) the grid truncation point, we consider (i) a power law turn on

\[ \epsilon(q) = \left[ (q - q_{0}) / (q_{\text{max}} - q_{0}) \right]^{n} q > q_{0} \] (2.9a)

and (ii) a Woods–Saxon potential

\[ \epsilon(q) = \frac{2 \lambda}{1 + \exp[(q_{\text{max}} - q) / \eta]}, \quad 0 < q < q_{\text{max}}. \] (2.9b)

A similar function is placed to the left of the interaction region \( (q < 0) \) in both cases.

The conditions and limitations on \( \epsilon(q) \) are that one wants it to turn on sufficiently quickly to absorb the flux over as short a distance as possible, but not to turn on sharply enough to cause reflection back toward the physically relevant region of space. These aspects were clearly discussed by Neuhauser and Baer\(^{2(1)(a)} \) for the case of a linear absorbing potential, i.e., \( n = 1 \) in Eq. (2.9a). Appendix B presents a discussion of these issues based on a semiclassical (WKB) treatment. \( \epsilon(q) \) is plotted in Fig. 1 for several choices of the parameters to be employed in the following calculations.

Physical intuition leads us to expect the second family of curves [Eq. (2.9b)] to better serve our purpose. The latter allows the low translational energy components, which suffer more from reflection, to encounter a shallow enough slope without forcing the magnitude of the absorbing potential to be unduly small. The quadratic curve of Fig. 1 is clearly an intermediate case between the constant \( n = 1 \) in Eq. (2.9a) \) and the exponential one [Eq. (2.9b)]. These expectations are borne out in Sec. III.

For a multidimensional system it is convenient to take \( \epsilon(q) \) as some one-dimensional function in Eq. (2.9),

\[ \epsilon(q) = \epsilon(q(q)), \] (2.10)
where $Q(q)$ is some function of all the coordinates $q$. The functional form of $\epsilon(Q)$ determines how the absorbing potential turns on upon entering the absorbing region as for the 1D case, and the choice of $Q(q)$ determines the location of the "absorbing strip" which surrounds (and defines) the interaction region. Examples of this are discussed more explicitly with regard to the application in Sec. III B.

C. Summary of methodology

The DVR grid points are laid down according to Eq. (2.2) and then truncated by the energy cutoff criterion, Eq. (2.4). An absorbing potential, Eqs. (2.9)-(2.10), surrounds (and defines) the interaction region. The DVR matrices of the kinetic $T$ and potential $V$ energies are given by Eq. (2.3) (the matrix $\epsilon$ is also a diagonal potential-energy-like matrix) and the DVR, or grid point representation for the Green's function, is thus

$$G(E^+) = (E \mathbf{T} V + i\mathbf{c})^{-1}. \quad (2.11)$$

The DVR matrix for the flux operator is given by Eq. (2.7), so that Eq. (1.5) for the cumulative reaction probability becomes

$$N(E) = 2\mathbf{r}^2 \text{tr}(\mathbf{F} \mathbf{G} \mathbf{F} \mathbf{G})$$

$$= 2\mathbf{r}^2 \left[ \text{tr}(\mathbf{F} \mathbf{G} \mathbf{F} \mathbf{G}^*) - \text{tr}(\mathbf{F} \mathbf{G} \mathbf{F} \mathbf{G}) \right], \quad (2.12)$$

where $G = G(F^+)$.  

Note added in proof. We have recently been able to show that the basic equation for $N(E)$, Eq. (2.12), can be cast in the following equivalent but simpler and more useful form:

$$N(E) = \text{tr}(\Gamma_r \mathbf{G} \Gamma_p \mathbf{G}^*), \quad (2.13a)$$

where $G$ is given by Eq. (2.11) (with $\epsilon = \Gamma/2$), and $\Gamma_r$, $\Gamma_p$ is the absorbing potential in the reactant (product) region; since these regions do not overlap, $\Gamma = \Gamma_r + \Gamma_p$. Because the absorbing potentials are diagonal in the DVR, this result can be also written as

$$N(E) = \sum_{\mathbf{k}'} \Gamma_r(q_j) \mathbf{G}_{\mathbf{k}' \mathbf{k}} \Gamma_p(q_{j'}) \mathbf{G}_{\mathbf{k} \mathbf{k}'}, \quad (2.13b)$$

which shows that only matrix elements of the Green’s operator between points $q_j$ in the reactant absorbing strip and $q_{j'}$ in the product absorbing strip are needed. Equation (2.13) also shows explicitly that $N(E)$ does not depend on the choice of the dividing surface [cf. Eq. (2.5) et seq.], so long as it lies between the reactant and product absorbing strips. Calculations of $N(E)$ for reactions in 3D space are being carried out using these expressions and will be reported in our next paper on this subject.

III. RESULTS AND DISCUSSION

A. One-dimensional results

It is useful to illustrate the convergence properties of the method described in Sec. II by first considering a 1D, analytically soluble model problem. In this subsection we present our results for the Eckart barrier

$$V(q) = V_0 \text{sech}^2(q/a) \quad (3.1)$$

(see Fig. 1). The barrier height $V_0 = 0.425$ eV and the mass

where $m = 1060$ a.u. are chosen to correspond approximately to the $H + H_2$ collision. For generality we measure distances in units of $a$.

Figure 2 illustrates the reaction probability, $N(E)$, using the Woods-Saxon form [Eq. (2.9)] with various values of $\gamma$ for the absorbing potential. The solid curve shows the exact probability

$$N_{\text{exact}}(E) = \left[ 1 + \left( \cosh(c)/\sinh(b) \right)^2 \right]^{-1}, \quad (3.2)$$

with

![Figure 2](attachment:image2.png)
\[ b = a \pi (2mE/\hbar^2)^{1/2}, \]
\[ c = (\pi/2) \left[ \left(8V_0ma^2/\hbar^2\right) - 1 \right]^{1/2}. \]

As shown in Fig. 2, the results are insensitive to the value of \( \eta \) over a wide range, \( 0.3a < \eta < 0.8a \), throughout the entire energy regime. Nevertheless, with too small a choice of \( \eta \) (the dotted-dashed curve in Fig. 2), the absorbing potential becomes steep enough to cause reflection, while with a very large \( \eta \) (the dashed curve of Fig. 2) \( \epsilon(q) \) penetrates the interaction region and interferes with the dynamics.

Figure 3 shows the reaction probability obtained using a linear absorbing potential \( [n = 1 \text{ in Eq. (2.9a)}] \) with several choices of \( q_0 \). Again, the exact curve is reproduced (to within 0.5%) using a range of \( q_0 \) values, \( 1a < q_0 < 4a \). When \( q_0 \) is increased beyond this range, the absorbing region allows some transmission (see Appendix B), while with too small a value of \( q_0 \) the imaginary potential is switched on early enough to deteriorate the reaction dynamics. It should be noted that a much larger grid is needed with the linear form (Fig. 3) as compared to that required with the Woods-Saxon potential (Fig. 2), in order to exhibit comparable insensitivity to the parameters of \( \epsilon(q) \).

Although accurate results can be obtained with widely different forms of the absorbing potential, the convergence properties of the method with respect to the grid size are clearly dependent on the form of \( \epsilon(q) \). As pointed out in Sec. II, for the present study it is of particular importance to minimize the size of the grid, not only for practical reasons, but also since the physical information required to compute the flux correlation expressions is expected to concentrate in a relatively small region, centered about the dividing surface.

In Fig. 4 we plot the percent error
\[ \frac{N_{\text{exact}}(E) - N_{\text{numerical}}(E)}{N_{\text{exact}}(E)} \times 100 \]
vs the grid dimension \( (q_{\text{max}}) \) using Eq. (2.9a) for \( \epsilon(q) \) with \( n = 1, 2, \) and 4. The (constant) energy is \( E = 0.32 \text{ eV} \) and the value of \( \lambda \) is chosen in each case so as to optimize the convergence rate. The corresponding absorbing potentials are shown in Fig. 1. As may be expected from Fig. 1, a broader absorbing region is needed to totally absorb the flux in the case of a linear form, as compared to that required using a quadratic function. The quartic form leads to poorer convergence, again a result which may be qualitatively anticipated from Fig. 1.

Figure 5 shows the percent error as a function of the grid dimension using the Woods-Saxon form for \( \epsilon(q) \). The corresponding absorbing potential is shown as a dashed curve in Fig. 1. The three curves of Fig. 5 correspond to three different energies: \( E = 0.32 \text{ eV} \), which is in the deep tunneling regime, \( E = V_c \approx 0.425 \text{ eV} \), and \( E = 0.76 \text{ eV} \), well above the reaction barrier. As the energy is increased, the system becomes more classical-like and less sensitive to the details of

---

**FIG. 3.** Reaction probability for the Eckart barrier using a linear absorbing potential, with \( q_{\text{max}} = 8.0a \): (---) Exact result [Eq. (3.2)]; (---) \( q_0 = 0.1a; (\bigcirc) q_0 = 1.0a; (---) q_0 = 4.0a; (---) q_0 = 6.5a.**

**FIG. 4.** Percent error in \( N(E) \) vs \( q_{\text{max}} \) at \( E = 0.32 \text{ eV} \), using Eq. (2.9a) for \( \epsilon(q) \): (---) \( n = 1 \); (-----) \( n = 2 \); (---) \( n = 4 \). The values of \( \lambda \) and \( q_0 \) in each case are as in the corresponding curve of Fig. 1.

**FIG. 5.** Percent error in \( N(E) \) vs \( q_{\text{max}} \) using the Woods-Saxon form for \( \epsilon(q) \): (---) \( E = E_0 \); (---) \( E = V_c \approx 0.425 \text{ eV} \); (---) \( E = 0.76 \text{ eV} \). The corresponding \( \epsilon(q) \) is shown as a dashed curve in Fig. 1.

---
the potential away from the saddle point. Consequently, the convergence rate improves rapidly. The low-energy curve of Fig. 5 compares favorably with the three curves of Fig. 4, in accord with our qualitative expectations based on Fig. 1.

In Fig. 6 we examine the convergence rate of $N(E)$ with respect to the density of grid points. Plotted is the percent error at several energies vs the number of grid points per deBroglie wavelength, $N_b = 2\pi/k\Delta r$, where $k = (2mE/\hbar^2)^{1/2}$. The number of grid points per wave required to attain $\pm 0.1\%$ accuracy is of the order of $N_b \approx 2.5-3.5$ at all energies. At low and intermediate energies the results converge at a somewhat higher value ($N_b \approx 3.5$), while the more energetic collisions require roughly 2.5 points per full wave. At still higher energies, $E > V_a$, the value of $N_b$ with which the results converge remains practically constant at 2.5.

### B. The collinear $H + H_2$ reaction

The $H + H_2$ collision serves as a standard test application for new methods, the major reason being the availability of an accurate potential surface and benchmark calculations for this system. In this section we present and discuss the results of calculations using the method described in Sec. II for the collinear $H + H_2$ reaction using the LSTH potential surface.24

A natural choice of coordinates for the present method, which centers attention in the vicinity of the saddle point, are the normal-mode coordinates of the transition state. The doubly infinite DVR grid is thus laid in these coordinates having to extend the grid into the reactant or product valleys. The number of DVR grid points per wave required to attain $\pm 0.1\%$ accuracy is of the order of $N_b \approx 2.5-3.5$ at all energies. At low and intermediate energies the results converge at a somewhat higher value ($N_b \approx 3.5$), while the more energetic collisions require roughly 2.5 points per full wave. At still higher energies, $E > V_a$, the value of $N_b$ with which the results converge remains practically constant at 2.5.

![Graph](http://example.com/graph.png)

**Fig. 6.** Percent error in $N(E)$ as a function of the number of grid points per deBroglie wavelength $N_b$. $\epsilon(q)$ is of the Woods–Saxon form with $\eta = 0.8a$ and $\lambda = 1.1$ eV: (---) $E = 0.76$ eV; (---) $E = 0.425$ eV; (---) $E = 0.32$ eV.

We have found that all three choices give correct results, but that the third choice, Eq. (3.3c), is the most efficient, i.e., leads to convergence with the smallest region and thus the fewest number of DVR grid points. The advantage of the configuration of Eq. (3.3c) [Fig. 7(c)] follows from the fact that the present approach allows us to focus attention on a relatively narrow strip along the dividing surface, without having to extend the grid into the reactant or product valleys.

For all calculations discussed in this subsection we have employed the Woods–Saxon form [Eq. (2.9b)] for the absorbing potential. Accurate results were also obtained using various powers in $q_2 - q_{2a}$ [Eq. (2.9a)]. The grid required was larger however, particularly in the high-energy regime, where more than a single vibrational channel is open, and the requirements of complete absorption and no reflection need be satisfied at more than a single translational energy. This effect may be qualitatively rationalized by inspection of Fig. 1.

The cumulative $H + H_2$ reaction probability, as calculated via Eqs. (2.9b)–(2.12) and (3.3c), is plotted vs the total energy in Fig. 8, and compared with the $R$-matrix propagation results of Bondi et al.25 The agreement is exact to within the degree of convergence of the results of Ref. 25 (±1% at the low energies and up to 5% at the high-energy edge).

Figure 9 examines more closely the behavior of the probability curve as the grid size is gradually reduced. Thus, with $q_{2a}^{max} = 3$ a.u. (corresponding to a total of 90 DVR points), the results have converged to better than 1% throughout the energy range examined. With $q_{2a}^{max} = 2$ a.u. [corresponding to the 64 grid points shown in Fig. 7(c)] the...
accuracy varies between 0.1% and 1.5%. Reasonable agreement with the exact curve at most energies is obtained with $q_2^{\text{max}} = 1.8$ a.u. and as few as 45 grid points.

Finally, in Fig. 10, we illustrate the convergence rate of the cumulative probability as a function of the grid dimension, $q_2^{\text{max}}$, and the energy cutoff parameter $V_c$. The percent error is computed with respect to the fully converged calculations of Zhang. The total energy is $E = 0.9678$ eV, about 0.19 eV above the threshold of the second vibrational channel.

The results shown in Fig. 10 converge to 0.02% with $V_c = 5$ eV and to about 0.5% when the cutoff parameter is halved to 2.5 eV. The former accuracy corresponds to a total
of 202, and the latter to a total of 104 grid points. A larger grid is required in the multiopen channels energetic regime as compared to the low-energy range considered in Fig. 9. This effect is due to the presence of the low translational energy \( E' \approx 0.19 \text{ eV} \) component. The latter requires that the slope of the absorbing potential be kept relatively small so as to avoid reflection. In order to completely absorb the high translational energy component the width of the absorbing region is then required to be larger (see Appendix B). Nevertheless, the total number of grid points required to attain \( \approx 0.5\% \) convergence in this less favorable energetic regime is encouragingly small.

IV. CONCLUDING REMARKS

The use of a discrete variable representation and absorbing boundary conditions provides a very convenient way of calculating the outgoing wave Green’s function \( G(E^+) = (E^2 - H + ie)^{-1} \). The primary advantage of this methodology over earlier variational basis set approximations\(^7\) for \( G(E^+) \) is that the present approach does not require any explicit information about the asymptotic channel states. The variational methods require that one includes basis functions that explicitly contain outgoing radial waves in each asymptotic open channel, while the ABC avoids this by absorbing all outgoing flux \textit{en route} to the asymptotic region. The absorbing potential, \( e(q) \), may be thought of as a generalization of the formal convergence parameter introduced in defining \( G(E^+) \) [Eq. \((1.5b)\)]. Allowing \( e \) to be a potential-energy-type operator thus provides much more flexibility in obtaining an efficient approximation for \( G(E^+) \); by having \( e(q) \) essentially zero in the physically relevant region of space, and nonzero only at the edges to absorb outgoing flux, one does not need to take the \( e \rightarrow 0 \) limit as when \( e \) is a constant. The approximation we obtain for \( G(E^+) \), however, is only valid for computing matrix elements \( \langle \Phi_2 | G(E^+) | \Phi_1 \rangle \) for states \( \Phi_1 \) and \( \Phi_2 \) localized to the interaction region.

Having \( G(E^+) \) available thus provides the microcanonical density operator \( \delta(E-H) \), Eq. \((1.5b)\), so that the flux-flux expression for the cumulative reaction probability, Eq. \((1.5a)\), can be readily evaluated. The results presented in Sec. III B for the benchmark reaction \( H + H_2 \rightarrow H_2 + H \) are quite impressive. One achieves convergence for the cumulative reaction probability with roughly one-quarter of the number of grid points needed to determine the state-to-state scattering (i.e., the \( S \) matrix).\(^10\) This is the “hoped for” efficiency of a “direct” calculation of the cumulative reaction probability provided by the flux-flux formalism.\(^1\)\(^2\)

Finally, as an aside, we note that the DVR-ABC representation of \( G(E^+) \) also provides the possibility of complete state-to-state scattering calculations, i.e., the reactive scattering matrix. Thus, let \( \Phi_i \) and \( \Phi_j \) be any distorted incoming waves for states \( i \) and \( j \), with asymptotic boundary conditions

\[
\Phi_i(r,R) \sim \sum_j \phi_j(r) \psi_i^{-1/2} (x) - e^{-ik_R \delta_{ij} + e^{ik_R S_{ij}^0}},
\]

and similar for \( \Phi_j \). Here \( R \) denotes the asymptotic (Jacobi) translational coordinate and \( r \) all the remaining internal coordinates. For clarity of notation we omitted the arrangement channel indices (which differ for states \( \Phi_i \) and \( \Phi_j \) in the case of a reactive collision). A formally exact expression for the \( S \) matrix is

\[
S_{ij} = S_{ij}^0 + \frac{i}{\hbar} \left[ \langle \Phi_j | H - E | \Phi_i \rangle + \langle \chi_j | G(E^+) | \chi_i \rangle \right],
\]

where

\[
\chi_i = (H - E) \Phi_i,
\]

\[
\chi_j = (H - E) \Phi_j.
\]

The distorted waves \( \Phi_i \), \( \Phi_j \) can be anything, from free (i.e., undistorted) waves

\[
\Phi_i(r,R) = \phi_i(r) \psi_i^{-1/2} (x) - e^{-ik_R} + e^{ik_R},
\]

with

\[
S_{ij}^0 = \delta_{ij},
\]

to the exact solution of the Schrödinger equation \( \Psi_i \) and \( \Psi_j \) with the boundary conditions of Eq. \((4.4)\), in which case \( S_{ij}^0 = S_{ij} \), the exact \( S \) matrix. In all cases the functions \( \chi_i \) and \( \chi_j \) of Eqs. \((4.3)\) are \( L^2 \) functions localized to the interaction region; they will be smaller, and presumably localized to closer in regions, the more accurately \( \Phi_i \) and \( \Phi_j \) approximate the exact wave functions \( \Psi_i \) and \( \Psi_j \). It is thus clear how one proceeds. The DVR-ABC approximation for \( G(E^+) \) is used in Eq. \((4.2)\). For the two-dimensional example treated in Sec. III B the explicit expression for the last term in Eq. \((4.2)\) is

\[
\langle \chi_j | G(E^+) | \chi_i \rangle = \mathbf{M}^j_i \cdot \mathbf{M}^j_i,
\]

where \( G \) is the DVR-ABC Green’s function of Eq. \((2.11)\), and

\[\text{FIG. 10. Percent error in the } H + H_2 \text{ cumulative probability at } E = 0.9678 \text{ eV, as a function of } q_{\text{max}}: (---) V_e = 5.0 \text{ eV}; (\cdots) V_e = 3.0 \text{ eV}; (\cdots\cdots) V_e = 2.5 \text{ eV}.\]
where \( FFBR \) is the basis set representation of Eq. (2.6d),

\[
F_{n,n'}^{FFBR} = \frac{\hbar}{2im} \left[ \psi_n'(0) \psi_{n'}'(0) - \psi_n'(0) \psi_{n'}'(0) \right].
\]  

Using Eqs. (A1) and (A4) in Eq. (A3) we find

\[
F_{n,n'}^{DVR} = \frac{\Delta q}{2im} \left( \cdot \frac{d}{d\mathbf{q}} - \cdot \frac{d}{d\mathbf{q}} \right),
\]  

where

\[
v_i = \psi_i(Q) = \delta(q_i) = \sum_n \psi_n(q_i) \psi_n'(0)
\]

\[
= \frac{1}{b} \sum_{n=1}^{N} \cos \left( \frac{n \pi q_i}{N} \right)
\]

\[
= \frac{1}{b} \sum_{k=0}^{N/2-1} \cos \left( \frac{2k \pi q_i}{N} \right) + \frac{1}{b} \sum_{k=1}^{(N-1)/2} \cos \left( \frac{2k \pi q_i}{N} \right).
\]  

APPENDIX A: ALTERNATIVE DVR FOR THE FLUX OPERATOR

We derive an alternative DVR for the flux operator, based on the special case of Eqs. (2.5b) and (2.6d). While the form suggested in the text [Eqs. (2.7)] has the formal advantage that it is manifestly independent of the coordinates, and the computational advantage that its matrix elements decay as \((j-i)^2\) away from the diagonal [compare Eqs. (A5)--(A9)], the form derived later is mathematically transparent and suggestive of the suitability of the grid representation for flux correlation expressions.

Following the standard DVR procedure, we first choose an appropriate finite-basis representation (FBR) for \(F_+\) \((\psi_n, n = 0, \ldots, N - 1)\), guided by the existence of a quadrature rule for evaluation of the potential matrix elements. Specifically, we choose a particle-in-a-box basis

\[
\psi_n(q_f) = \sqrt{\frac{1}{b}} \sin \left( \frac{n \pi q_f}{2b} \right)
\]  

\[
(1 - \delta_{j,0}) \Delta q_a^{-1}
\]

\[
d_j = d_j(0) = \delta'(q_f) = \sum_n \psi_n(q_f) \psi_n'(0)
\]

\[
= \frac{1}{b} \sum_{n=1}^{N} \cos \left( \frac{n \pi q_f}{N} \right)
\]

\[
= \frac{1}{b} \sum_{k=0}^{N/2-1} \cos \left( \frac{2k \pi q_f}{N} \right) + \frac{1}{b} \sum_{k=1}^{(N-1)/2} \cos \left( \frac{2k \pi q_f}{N} \right).
\]  

The \(\psi_n(q_f)\) form a grid representation for the coordinate operator, and the \(\mathbf{F}(\mathbf{q}_f)\) form a grid representation for the velocity. Equation (A5) is thus a direct DVR transcription of Eq. (2.6d).

Summing Eqs. (A6) and (A7) over \(k\) [Ref. (28), Eqs. (1.342.1), (1.342.2), and (1.352.1)] we find

\[
v_i = \delta_{j,0} \Delta q_a^{-1}
\]

\[
d_j = (1 - \delta_{j,0}) \frac{\pi}{h} \left[ \frac{\sin \left( \frac{\pi q_f}{N} \right)}{\sin \left( \frac{\pi q_f}{N} \right)} - (N + 1)(-1)^j \right]
\]

\[
+ \frac{N - \omega}{j} \Delta q_a^{-2} \left[ (1 - \delta_{j,0}) \Delta q_a^{-1} ight]^{-1}
\]  

Equation (2.3c) in the text may be derived similarly, by transforming the basis set representation of the kinetic-energy operator,

\[
T_{n,n'}^{FFBR} = \delta_{n,n'} \frac{\hbar^2}{2m} \left( \frac{n \pi}{2b} \right)^2
\]

using the analogous relation to Eq. (A3).
APPENDIX B: WKB DESCRIPTION OF THE REFLECTION AND TRANSMISSION BY AN ABSORBING POTENTIAL

We consider a one-dimensional system in a region where the actual (real) potential \( V(q) \) is zero. The net effective potential \( V(q) - i\epsilon(q) \) is thus the (imaginary) absorbing potential alone, i.e.,

\[
V_{\text{eff}}(q) \equiv V(q) - i\epsilon(q) = -i\epsilon(q),
\]

and we assume the power law form of Eq. (2.9a) for \( \epsilon(q) \)

\[
\epsilon(q) = \begin{cases} 
0, & q < q_0 \\
\lambda \left( \frac{q - q_0}{q_{\text{max}} - q_0} \right)^n, & q > q_0.
\end{cases}
\]

The WKB approximation for the probability that a particle incident from the left, \( q_{\text{initial}} = q_1 < q_0 \), and moving to the right (+ \( q \) direction) is reflected back to position \( q_1 < q_0 \), i.e., the reflection probability \( R \), is given by

\[
R = \left| \exp \left( 2i \int_{q_1}^{q_0} dq k(q) \right) \right|^2 = \exp \left( -4 \text{Im} \int_{q_0}^{q_1} dq k(q) \right),
\]

where \( k(q) \) is the (complex) local momentum (in units of \( \hbar \))

\[
k(q) = \left( \frac{2m}{\hbar^2} \left[ E - V_{\text{eff}}(q) \right] \right)^{1/2},
\]

and \( q_1 \) is the (complex) turning point

\[
k(q_1) = 0.
\]

In light of Eq. (B1), \( k(q) \) is given by

\[
k(q) = k \left[ 1 + i\epsilon(q)/E \right]^{1/2},
\]

where \( k = (2mE/\hbar^2)^{1/2} \), and with \( \epsilon(q) \) given by Eq. (B2) one finds the complex turning point to be

\[
q_1 = q_0 + (q_{\text{max}} - q_0) \left( \frac{E}{\lambda} \right)^{1/n} e^{\pi i 2n}.
\]

With Eq. (B5), Eq. (B3) can be evaluated to give

\[
R = \exp \left( -4k(q_{\text{max}} - q_0) \left( \frac{E}{\lambda} \right)^{1/n} C_n \right),
\]

where the constant \( C_n \) is

\[
C_n = \sin \left( \frac{\pi}{2n} \right) \frac{\Gamma(1 + 1/n) \Gamma(3/2)}{\Gamma(1/n + 3/2)}.
\]

Similarly, the WKB approximation for the probability that the same particle (i.e., incident from \( q_1 < q_0 \), and moving to the right) reaches the position \( q_{\text{max}} \), i.e., the transmission probability \( T \), is

\[
T = \left| \exp \left( i \int_{q_0}^{q_{\text{max}}} dq k(q) \right) \right|^2 = \exp \left( -2 \text{Im} \int_{q_0}^{q_{\text{max}}} dq k(q) \right).
\]

With \( \epsilon(q) \) given by Eq. (B2), and \( k(q) \) by Eq. (B5a), this can be written as

\[
T = \exp \left( -2k(q_{\text{max}} - q_0) \right) \times \text{Im} \int_{q_0}^{q_{\text{max}}} dq \left( 1 + i\epsilon(q)/E \right)^{1/2},
\]

which can be evaluated analytically only for the linear and quadratic cases. In general, one sees that the reflection and transmission probabilities of Eqs. (B6a) and (B8) depend only on two dimensionless parameters: \( S \), the strength of the absorbing potential in units of \( E \),

\[
S = \frac{\lambda}{E},
\]

and \( W \), the width of the absorbing region in units of \( k^{-1} \),

\[
W = k(q_{\text{max}} - q_0).
\]

In terms of these dimensionless parameters, Eqs. (B6a) and (B8) read as

\[
R = \exp \left( -4C_n \frac{W}{S^{1/n}} \right),
\]

\[
T = \exp \left( -2W \int_{q_0}^{q_{\text{max}}} dq \text{Im} \left( 1 + iS^2 \right)^{1/2} \right).
\]

The physical considerations are that one wants \( R \) and \( T \) to be small, i.e., one wants no particles to be reflected by the absorbing potential (\( R < 1 \)) and all the flux to be absorbed over the interval \( (q_0, q_{\text{max}}) \) (\( T < 1 \)). For example, if one wishes to have

\[
R = T = 10^{-l},
\]

where \( l \) is a predetermined tolerance, Eq. (B10) implies that

\[
4C_n \frac{W}{S^{1/n}} = 2.31,
\]

\[
2WG_n(S) = 2.31,
\]

where \( G_n(S) \) is the function

\[
G_n(S) = \int_0^1 dq \text{Im} \left( 1 + iS^2 \right)^{1/2}.
\]

To solve Eqs. (B12) one first eliminates \( W \) to obtain a single equation for \( S \)

\[
S^{1/n}G_n(S) = 2C_n,
\]

which is seen to be independent of the accuracy required in Eq. (B11) (i.e., how small \( R \) and \( T \) are required to be). After \( S \) is determined by solving Eq. (B14) (numerically), \( W \) is given by Eq. (B12a)

\[
W = 2.31S^{1/n}G_n(S) = 4C_n.
\]

and seen to be proportional to the “accuracy exponent” \( l \).

Figure 11 shows the strength parameter \( S \) [Eq. (B14)] and the corresponding width parameter [Eq. (B15)] for \( l = 3 \), as a function of \( n \), the power in Eq. (B2). Since one wishes the width of the absorbing potential to be as small as possible, possible, Fig. 11 shows the optimum power to be \( n = 1.5 \) and the corresponding minimum value of \( W \) to be approximately \( 2\pi \). Thus, the width of the absorbing region needs to be at least 1 deBroglie wavelength,
in order to achieve \( T, R < 10^{-3} \).

The aforementioned WKB estimates may serve as qualitative guidelines for the choice of the absorbing potential parameters in the general multidimensional case. They should not, however, be interpreted quantitatively for other than a 1D problem with a power-law choice for \( \epsilon(q) \), for two reasons. First, one wishes to apply the absorbing boundary conditions in regions where the physical potential differs from zero. Second, in practical systems more than a single channel is typically open and, therefore, the conditions of complete absorption and no reflection should be satisfied at more than a single translational energy. In practice, therefore, one needs to carry out convergence checks to determine the optimum form of the absorbing potential.
